Abstract

Background: The importance of the respiratory system in swimming is recognized by sports scientists. However, the effects of swimming techniques on the respiratory system have not been adequately investigated.

Objective: Thus, the present study aimed to investigate the acute effects of four different swimming techniques on inspiratory strength, endurance, and fatigue.

Methods: For this purpose, 18 young competitive swimmers participated in this study. First, baseline values in the respiratory system of the swimmers were determined for the control measurement without swimming. In the experimental measurement, the subjects performed four different swimming techniques randomly. After the swimming techniques were performed, inspiratory strength, endurance, and fatigue tests were carried out immediately. Repeated-measures one-way analysis of variance and least significant difference tests were used for statistical analysis.

Results: The four different swimming techniques had decreased the respiratory muscle strength and endurance and had increased the respiratory muscle fatigue (p < 0.05). In addition, the negative effects of front crawl and butterfly-style swimming techniques were higher than those of other techniques (p < 0.05).

Conclusion: In conclusion, the four different swimming techniques adversely affect respiratory muscle strength, endurance, and fatigue. The main sources of these effects are natural resistance to exercise, water pressure, and horizontal position in swimming.

Keywords: Swimming; Respiratory; Strength; Fatigue; Endurance

Introduction

The respiratory system is the main component of aerobic capacity [1,2]. Oxygen consumption and related cardiorespiratory parameters have been traditionally used to study the energetics of swimming in humans [3-5]. The respiratory system, which is important in daily life and determining work performance, is also important in terms of sportive performance capacity [6]. Unlike all sports, swimming

Citation: Bilal Coşkun, et al. "Acute Effects of Four Different Swimming Techniques on Inspiratory Strength, Endurance, and Fatigue". EC Pulmonology and Respiratory Medicine 10.3 (2021): 64-75.
is performed in a horizontal position. Thus, in this activity, the respiratory system faces difficulties because of the water pressure. During swimming, breathing is performed by inhaling orally and exhaling through the nose. For this reason, breathing training is important in swimming [7-9]. Previous studies have demonstrated the positive effects of swimming on the respiratory system [10-13].

Physiologically, muscle fatigue provides important improvements in muscle endurance with regular trainings [6]. Resistance of the respiratory muscles exposed to the water causes fatigue, and if swimming is performed regularly, respiratory muscle endurance increases [5,14]. Respiratory muscle fatigue is a contributing factor in reducing endurance exercise performance [15-17]. Altogether, these studies suggest that swimming, similar to other forms of physical exercise, has a beneficial effect on aerobic performance and exercise tolerance [18,19].

Most studies focused on the effect of the respiratory system on swimming performance. On the contrary, the present study aimed to investigate the acute effects of four different swimming techniques on respiratory strength, endurance, and fatigue. In the current study, not only the effect of swimming on respiratory functions but also the effect of respiratory muscle strength, endurance and fatigue were investigated. We hypothesized that the swimming techniques will have negative effects on inspiratory muscle strength, endurance and fatigue.

Materials and Methods

Subjects

Eighteen male swimmers aged 18–20 years old volunteered to participate in the study (Table 1). A priori test with GPower 3.1 program was used for determining the number of participants. The aim of the study was explained to all subjects and a written informed consent was obtained from all subjects in the familiarization session. Exercise and high-intensity physical activity were prohibited before the trials. The subjects avoided alcohol, caffeine, and exercise 24 h prior to testing. Inclusion criteria included having been a competitive swimmer and practicing regular swimming exercise 5 days/week for at least 4 years.

Research design

This study was developed as a randomized, double-blinded, cross-experimental design with practice-controlled repeated measurements. The study design included one familiarization session followed by five repeated testing sessions for all subjects. During the familiarization session, the participants experienced laboratory-based tests of maximal inspiratory pressure (MIP, for inspiratory muscle strength and fatigue), maximal voluntary ventilation (MVV, twice for inspiratory muscle endurance) tests, and expected 50m sprint swim with four different techniques. The subjects were subjected to the second session in the laboratory for the control measurement to deter-
Acute Effects of Four Different Swimming Techniques on Inspiratory Strength, Endurance, and Fatigue

mine the basic values without swimming performance. Subsequently, the subjects were performed four 50m sprint swimming sessions with four different swimming techniques (front crawl, backstroke, butterfly, and breaststroke) randomly with 24h interval. The sessions were applied at the same time (between 12:00 and 14:00) each day. The present study was designed and implemented in accordance with the Declaration of Helsinki [20]. Approval was obtained from a local clinical research ethics committee (Gaziantep University, Clinical Research Ethics Committee, 2017/94).

Sprint swimming performance (50 M) with four swimming techniques

Participants completed 50 m swimming with four techniques (front crawl, backstroke, butterfly, and breaststroke) starting from a stationary position on the pool starting blocks, as in official competitions. Swimming was completed individually in a 25 m indoor pool, and performance times were measured with a single stopwatch by an experienced time-keeper (swimming referee). Participants were instructed to complete the performance as fast as possible, and strong verbal encouragement was provided throughout the testing [21].

Maximal voluntary ventilation measurement

The subjects wore nose clips and breathed deeply (greater than the tidal volume but lower than the vital capacity) and rapidly for 15s with a spirometer (Pocket Spiro USB100, Medical Electronic Construction R&D, Brussels, Belgium). After the first three breaths, the subjects were actively encouraged to maintain the same volume and frequency by following an on-line display of the maneuver on a computer screen. At least two acceptable maneuvers were obtained, and after flow integration, the highest value was recorded by extrapolating the 15 s accumulated volume to 1 min MVV (L/min) [22].

Inspiratory muscle strength measurement (MIP)

MIP was measured with a respiratory pressure meter (PocketSpiro MPM-100, Medical Electronic Construction R&D, Brussels, Belgium) to indicate respiratory muscle strength in accordance with the 2002 guidelines of the European Respiratory Society and American Thoracic Society. Measurement started from the residual volume. The nose was occluded throughout the measurement. To obtain the best values, all subjects performed three to five attempts with no more than a 5% difference between two attempts. An average of three acceptable attempts was used as the MIP value [23].

Determination of inspiratory muscle endurance

Respifit S (Biegler GmbH, Mauerbach, Austria) respiratory muscle training device was used for the exercise of respiratory muscle endurance.

Inspiratory muscle endurance exercise procedure:

- After the nose airway was closed with a clip, the mouthpiece of the device was given to the subject, who then performed forced inspiration and expiration for 5x1 min by following the warnings and commands on the device screen [24].

Determination of inspiratory muscle endurance:

- MVV was measured before (MVV1) and after (MVV2) the inspiratory muscle endurance exercise. The percentage difference from MVV1 to MVV2 (MVV2/MVV1) was used considered the respiratory muscle endurance [25].

Determination of respiratory muscle fatigue

The percentage difference between respiratory muscle strength values measured before and after each swimming exercise was accepted as the respiratory muscle fatigue [26].
Statistical analysis

SPSS 22.0 program was used for statistical analysis. Shapiro-Wilk test was used for normality testing and Levene’s test for homogeneity. Repeated-measures one-way analysis of variance and least significant tests were performed to determine the acute effect. The data were expressed as the mean, standard deviation, and standard error, and significance was defined as $p \leq 0.05$.

Table 2 shows that the differences in the respiratory muscle strength (MIP) between the swimming techniques. Significant differences were observed among groups (control, front crawl, back crawl, butterfly, and breaststroke) in terms of respiratory muscle strength ($p < 0.05$). The results showed that the respiratory muscle strength decreased after the swimming performance, with more decreased respiratory muscle strength attributed to front crawl and butterfly swimming (Figure 1).

Table 3 shows the differences in the respiratory muscle fatigue (MIP) between the swimming techniques. Significant differences in respiratory muscle strength were noted among groups (control, front crawl, back crawl, butterfly, and breaststroke) (p < 0.05). The swimming performance increased respiratory muscle fatigue due to the decreased respiratory muscle strength. Especially, the front crawl and butterfly swimming performance caused more respiratory muscle fatigue compared to other swimming techniques (Figure 2).

Table 6 shows the differences in respiratory muscle endurance between the swimming techniques. Significant differences in MVV after respiratory muscle exercise were observed among groups (control, front crawl, back crawl, butterfly, and breaststroke) (p < 0.05). The results showed that respiratory muscle endurance, which was determined as a result of respiratory muscle exercise, decreased after swimming performance. Especially, the front crawl and butterfly swimming performance more negatively affected respiratory muscle endurance compared with the other swimming techniques (Figure 5).
Discussion

This study aimed to determine the influence of the acute effects of four different swimming techniques on inspiratory strength, endurance, and fatigue using a cross-experiment design with practice-controlled repeated measurements. Two major findings were obtained in the present study: first, all swimming techniques negatively affected inspiratory muscle strength, endurance, and fatigue; second, front crawl and butterfly swimming techniques showed the highest negative effects.

Swimming exercise has acute adverse effects on inspiratory muscle strength. It is thought to be the luck tiredness because of the negative effect. The increased muscle temperature, decreased pH, and intramuscular and blood hemostasis are associated with acidosis and decrease the performance ability of respiratory muscles [27].

Swimming as a sport causes acute negative effects on respiratory ventilation [8] and increases blood lactate level [28] and serum level of hormone-related stress [29-34]. The reduction of respiratory muscle strength and endurance to pressure water [8] may cause insufficient blood supply to the muscles and insufficient oxygen [16,35]. Insufficient oxygen supply to the muscles and high levels of exercise can prevent the healthy contraction of muscles [36]. Given that swimming effectively works on core region muscles, it also affects lung volume and capacity [37]. This effect is partly due to water pressure; however, the most important effect is that swimming is performed in a horizontal position [38]. Pressure and posture factors create stressor effects [31,33,39].

In addition to the factors mentioned above, the present findings may be attributed to different reasons. Hypoxia occurs due to resistance to water, and this condition is restricted to medulla obstruction. Thus, adaptation is provided by increasing the frequency and depth of respiration [40]. On the other hand, along with water pressure and high external pressure to the chest region that occur in swimming, resistance develops by decreasing the mechanical operation of the diaphragm [41,42]. Several studies claimed that inspiratory muscle training after exercise may alleviate respiratory muscle fatigue and increase respiratory muscle endurance. In addition, follow-up inspiratory muscle training increases blood flow and oxygen transport to the working muscle [43,44]. These stressor effects result in decreased inspiratory muscle strength and endurance and increased inspiratory muscle fatigue.

In addition, given the amount of muscle and rate of contraction used in butterfly swimming style, butterfly swimming technique is accepted as the most difficult swimming technique [45]. This information shows that butterfly-style swimming has a negative effect on respiratory muscles.

Conclusion

In conclusion, in the present study, fatigue was assumed to be the main cause of the acute negative effects of swimming exercise on respiratory muscle strength, endurance, and fatigue. The main sources of fatigue are natural resistance to exercise, water pressure, and horizontal position in swimming. The number of muscles used and the contraction rates are the reasons for the differences between techniques. In summary, different techniques of swimming exercises acutely affect the respiratory muscle strength, fatigue, and endurance, and butterfly swimming style has more negative effects on respiratory muscles.
